**Introduction**

The allis shad is one of Europe’s most vulnerable species. At the beginning of the twentieth century, it could be found in large shoals in almost all of the major river systems which flow into the Atlantic, the North Sea and partly those flowing into the Mediterranean Sea.

The distribution area stretched from North Africa to southern Scandinavia. Due to often rigorous overfishing, coupled with increasing environmental degradation through water pollution, development and the progressive construction of weirs and dams, which block access to their spawning grounds, this species has died out in large parts of Europe within the span of only a few decades. Vital remaining stocks of this species have survived in some western French, Portuguese rivers and one Moroccan river system.

The allis shad in these waters are still commercially important today and feed many fishing enterprises. Until 2007, this was also true for the hitherto largest remaining stock of allis shad in the French Gironde-Garonne-Dordogne system, also known as the donor population selected for the first stocking project of allis shad to date, the LIFE project „Re-introduction of shad to the Rhine System“ (LIFE06 NAT / D / 000005).

While an average of about half a million allis shad still migrated to spawn in the Garonne and Dordogne in the 1990s, the stock collapsed dramatically early in the new millennium. Since then the population has been reduced to less than one percent of that number. The identification of the reasons for this development, in addition to the continuation and documentation of the success of stocking activities in the Rhine, is the aim of the Life+ project „Conservation and Restoration of the Allis shad in the Rhine and Gironde Watersheds“. The project has two distinct and yet inseparable pilot measures in order to protect the stocks of Alosa Alosa: the aim of preserving the reintroduction of the species in its former area of distribution and the investigation of the reasons for the decline of the largest remaining population with the aim of maintaining and improving the stock situation of allis shad in Europe.

The measures are jointly coordinated by the LANUV and the Rhenish Fisheries Federation from 1880 and implemented in cooperation with partners in the French Aquitaine, the Netherlands and in the German federal states North Rhine-Westphalia and Hesse.
The collapse of allis shad populations in the Gironde region

As late as the turn of the millennium, around half a million adult allis shad migrated to the Garonne and the Dordogne in order to spawn. At that time the delicious allis shad still constituted the most economically important target species of the numerous fishing companies in the Gironde region, which used about half of the stock. The year 2003 seems to have been a turning point for the allis shad stock — indeed still a few hundred thousand adult allis shad migrated to the rivers at that time, but unlike previous years, a far lower number of migrating juvenile fish could be found in the Gironde estuary for the first time in 2003.

In order to be able to understand this development, it is necessary to take a look at the complex life cycle of the species under the microscope.

The allis shad is an anadromous migratory fish, which belongs to the same family as the herring and herring-type fish (Clupeidae), and spend most of their lives in the sea. Mature allis shad migrate to spawn in the middle reaches of rivers (barbel region). When the water temperature rises above 11°C, the allis shad gather together in the estuaries and migrate up the rivers. The fish spawn in the spring, when the water temperature rises above 15°C, from April to July and especially in the month of May (this is the reason for the German name of ‘May fish’!). Spawning areas are moderately flowing gritty river sections, such as those found on the inner bend banks, overflown gravel banks or at the mouths of tributaries. The peculiar spawning takes place at night directly on the water surface. The allis shad beat their tail fins in circular swimming movements on the surface of the water. The vociferous splashing can be heard from a long distance. The fertilised eggs sink to the bottom and are deposited in gaps in the gravel substrate. It takes about four to five days for the eggs to hatch. Afterwards, the young fish remain in the rivers for a few weeks or months and migrate to the brackish areas of the estuaries in late summer / autumn. They migrate into the sea from these areas no later than winter, where they grow to maturity in three to seven years and complete the life cycle with a renewed migration to the rivers.

The decline in the young-of-the-year fish population (fish that are hatched in the same year) observed in the Gironde estuary in autumn 2003, which was finally reflected from three years later on in a similarly dramatic decline of the stock of sexually mature allis shad from this generation returning from the sea. The decline in stocks in the Gironde-Garonne-Dordogne system can most probably be explained by an insufficient spawning success since that time or the increased mortality of juvenile fish prior to their arrival in the estuaries.
One possible explanation for reduced spawning success might be the lack of suitability of the fishways on the dams of the Garonne and Dordogne. Due to the fact that only a small proportion of the allis shad population is able to overcome the dam structures in order to reach the major spawning areas of the rivers, the shads are forced to reproduce in the inferior spawning areas which lie below the dams in the lower reaches. As the gravel and the bed load are trapped in the barrage sections and are not transported further downhill, significantly less favourable reproduction conditions for allis shad can be found in the lower reaches because their eggs cannot deposit in these essential gaps between pieces of gravel, where they can develop until the larvae hatch. There were indeed possible deficits in the fishways when the stock was still vigourous, however, it could be observed that the number of allis shad negotiating the fishways decreased with the size of the stock, so that fewer and fewer fish were spawning on the more effective productive spawning grounds in the middle reaches of the rivers. Studies on the use of existing fishways by allis shad, which were caught on the fishways and provided with radio telemetric transmitters before being released again downstream, point to significant deficiencies in terms of discoverability and attractiveness of the three fishways investigated. Only one of the 222 allis shad equipped with transmitters managed to negotiate one of the fish ladders. The fishway concerned, the slot pass at the weir in Bergerac on the Dordogne, was easier to evaluate than the fish lifts in
Tuilières and Golfech, also with respect to other parameters such as the number of entry attempts and the residence time of the allis shad in the fishway.

A shoal of allis shad in search of the downstream entrance of the fishway at the Bergerac dam on the Dordogne

Searching for tagged allis shad in the river course

Overall, the suitability of the investigated fishways relevant for the allis shad in the Gironde region seem very limited. Similar problems also appear in the more modern and significantly larger fish migration facilities at rivers used by shad (here concerning the American allis shad) on the US east coast, as were revealed by a joint evaluation of the functional checks by American, Canadian and French fishway experts from the Life+ project team. The optimisation of fishways for the allis shad therefore has a key function for the (re)development of spawning areas and the conservation
of the allis shad. Based on these findings, the functioning of the existing fish migration facilities should be improved in the coming years and additional fishways should be constructed on the dam structures in Garonne and Dordogne where possible.

Although the three dams on the river Dordogne in Tuilières (upper left), Mauzac (lower left) and Bergerac (right) are equipped with fishways, only a minor part of the allis shad population is able to pass the dams. The same applies to the dam at Golfech on the Garonne river.

**Condition of juvenile fish populations in the rivers**

Another possible hypothesis for the collapse of the allis shad population, which has been explored within the framework of the Life+ project and could explain the decline of juvenile fish stocks in the Gironde estuary in autumn since 2003, is the deterioration of living conditions in the rivers and increased mortality of juvenile fish during the first weeks of life. This could be caused by, for example, changes in the conditions of the physical habitat, such as the composition of the soil substrates or food availability. A complicating factor when investigating this issue is that it was not possible to sample the juvenile stages of allis shad in the past, or even to quantify their populations, which is due particularly to their pelagic way of life. Scientists repeatedly succeeded in finding evidence of juvenile allis shad with specially designed push and drift-nets. River sections below spawning grounds in the Garonne and the Dordogne were examined in a study. Due to the continuing decline in the number of mature allis shad returning from the sea at the start of the investigations, which sank to an all-time-low in the years 2012 to 2015, the natural breeding volume was so low that in total only a few juvenile fish were detected, and a quantification of stocks and comparative analysis of the influence of conditions for growing to maturity on population density was not possible. In this respect, the small number of detected juvenile allis shad reflects the dramatic population trends and their limited self-renewal to a large extent.

Danger in the lower reaches of rivers

Another factor of great importance for the insufficient self-renewal of the stock is recruitment, which has emerged as a consequence only in recent years: Because of the extreme heat wave and the record low water levels in 2003, the so-called Bouchon Vaseux (silt plug) formed from suspended fine sediments in the tidal-influenced lower reaches of the river. Due to the retention of the outflow in reservoirs and dams, there were hardly any floods in the rivers which could flush this mud cloud out into the open sea. Because of the constant supply of fine sediments from farmland in the catchment area, especially cornfields, the Bouchon Vaseaux survives and regenerates itself, and it represents an increasing problem for the communities in the area of the tidal-influenced lower river reaches.

A particular problem here is the accumulation of oxygen-consuming particles, which means that there is a lack of oxygen in the Bouchon Vaseux area in summer and autumn, i.e. during the periods in which the juvenile allis shad are undertaking their migration to the sea through the lower river reaches. It seems reasonable to suppose that only a few of the juveniles migrating through the zone of the Bouchon Vaseux survive the journey unscathed and therefore the recruitment is also diminished. While the investigation of this factor is not the subject of the Life+ project, it is, however, likely to be of great importance for the allis shad population in the Gironde region and should become a stronger focus of future action, especially as a similar problem has also been occurring in other European river estuaries.

Location of the mud plug (Bouchon vaseux) in the tidal influenced downstream part of the river Gironne around the city of Bordeaux

Percentage of days per month and year in which hypoxia (< 5mg O₂/l) occurred in the mud plug section of the Gironne. Particularly in August and September, when the YOY shads must pass through the Bouchon vaseux to reach the estuary, they encounter critical conditions.
Continuation and review of the success of the resettlement activities in the Rhine system

With the LIFE project „The re-introduction of allis shad in the Rhine“, the foundations and infrastructure for Europe’s first project for the re-introduction of allis shad in its former distribution area have been created with the help of the development of mass breeding, transportation and stocking techniques and the construction of an allis shad farm in Aquitaine. From 2008 to 2010 about five million allis shad larvae bred in France were released into the Rhine system for the first time (see LANUV Technical Report 28). The stock fish were taken from the Gironde-Garonne-Dordogne population. Allis shad which are ready to spawn are caught during the spawning migration in the Garonne and Dordogne, and brought to reproduce in the breeding facility near Bruch in the Aquitaine. The aim to make adult fish return from the stocking programme and founding a population the restocking measures are continued as part of the Life+ project from 2011 onwards. by Other key measures in the Rhine catchment area were studies on the behaviour of young allis shad after restocking, the search for the first adult allis shad from the restocking of the first Life project, which should return as of 2013, as well as exploring the possibility of raising allis shad in breeding stocks to sexual maturity in order to be able to increasingly draw on „ex situ“ stocks in future restocking programmes and therefore become more independent of the offspring from wild stock.

Breeding and stocking of allis shad

Allis shad breeding is carried out at the breeding facility in Bruch in the Aquitaine. The French project partner association MIGADO, which also conceived and built the breeding facility for the preceding LIFE Allis shad project, is responsible for catching the parent fish in the Garonne and Dordogne and the work involved in the breeding and transportation of the allis shad larvae.

The breeding techniques have been optimised to the extent that around 80 parent fish need to be taken from the Garonne and Dordogne in order to breed two million allis shad larvae for stocking in the Rhine. This number corresponds to approximately one percent of the size of the spawning stock and has no impact on the natural population size in the Gironde region. After being caught, the parent fish are administered a hormone which which speeds up the maturing and the fish are soon able to spawn independently after their arrival at the fish farm and transfer into a spawning pool. The fertilised eggs are incubated for a few days in breeding jars before the allis shad larvae hatch from the eggs. Soon after hatching, the larvae are transferred into a solution containing with the fluorescent substance oxytetracycline, which is incorporated in bony structures such as otoliths and makes it possible later on to identify the fish which have come from the breeding facility. The larvae are then transported to Germany at the age of 5 to 20 days to be released in waters in the Rhine system. A total of around 6.2 million allis shad larvae were produced and transferred into the Rhine system between 2011 and 2015. In the years
in which damp, cool weather and flood conditions prevailed in the Gironde region, the breeding success was significantly lower than in friendly hydro-climatic conditions. In addition, as due to the stock situation only a limited number of parent fish could be taken, the stock shortage was under a million in three of these years. As the stock was dependent on the conditions in the Rhine basin (water level and flow, presence of competitors and potential predators etc.), certain waters were selected in order to guarantee the optimal chances of survival for the young allis shad larvae. Based on the experience of the first stocking year, after transportation to the river the allis shad were kept in circular tanks and fed until the evening in order to facilitate adaptation to the new habitat and guarantee higher survival rates.
Conservation and restoration of the Allis shad in the Gironde and Rhine watersheds

Feeding of the allis shad larvae in the tanks
Monitoring of juvenile fish after restocking

The studies on the behaviour and habitat use of the young allis shad following stocking are aimed at evaluating the stocking strategy and assessing the survival rates and optimisation of the stocking programme. Similarly to the search, which was carried out at the same time, and previous studies of the juvenile fish in the river habitats in the Gironde region, it could be seen how difficult it is to track the juvenile stages of allis shad by monitoring the restocked waters. Despite intensive studies, which were carried out immediately after restocking and in the vicinity of the stocking locations using fine-meshed drift, push and seine nets, they did not provide any new insights on the behavior of allis shad larvae, which apparently spread in small shoals and created ‘niche partitioning’ after restocking or natural hatching. It is difficult to find evidence of them, especially given their small number in comparison to the immense habitat area. This appears to apply to an even greater extent to the juvenile stages, which were searched for in the weeks following restocking using push, drift and fixed nets in accordance with the expected size of the fish, as well as electro-fishing from the area of the restocking locations up to several kilometres around them. Despite the considerable amount of work and time spent, there was no success in recapturing the allis shad. Nevertheless, evidence finds of juvenile allis shad in the by-catches of an anchored stow-net in the mid and lower Rhine and in the cooling water intakes of power plants along the Rhine showed that the juveniles were able to find good growing conditions in the Rhine system and migrate to the sea in autumn.

Pilot facilities for ex situ stock

In order to guarantee stocking measures for Alosa alosa in future regardless of the exploration of the wild stock, the pilot facilities have been put into operation for ex situ stocks. In these pilot facilities, the aim is to grow allis shad larvae from the breeding facility in Bruch to juveniles and finally to adult, sexually mature fish, in order to use these as future breeding stock for the production of stocking fish. The success of this method is not certain due to the complex life cycle of the species and their stay at sea over several years. Part of the study, which is implemented at two sites in Aßlar (Germany) and in La Rochelle (France), is to investigate the importance of food composition, salinity and water temperature as well as the influence of the circadian rhythm on the growth and development of sexual maturity. The growth of the allis shad in the pilot facilities has been encouraging. The fish in Aßlar reached a total length of 20 cm in their first year and the two-year old allis shad had already grown to 33 cm. At the La Rochelle site, the development of sexual maturity under farm conditions is being followed by accompanying histological and physiological studies. It appears that the sexual organs of the allis shad in the farm have been developing normally. The first males were sexually mature at the age of four, with a length of 32 cm. Despite this satisfying result, there still remains a lot of work to be done for the development of efficient breeding in ex situ stocks. So far, it is unclear whether the fish living under farm conditions have high fecundity (number of eggs per individual) and how large the stocks would need to be in order to produce the required number of allis shad larvae for stocking. Furthermore, it needs to be clarified whether the complex mechanism of the development of maturity can be simulated under farm conditions. Problems are still posed regarding the function of the biofilters in recirculating systems with changing salinity values, and the nutrient supply to the demanding allis shad under farm conditions. A study conducted by scientists at the University of Giessen on the nutrition optimization of juvenile allis shad showed that the phenomenon of jaw deformity and extreme nervousness of the fish repeatedly observed in the past can be prevented by an appropriate diet with probiotic bacteria and certain essential fatty acids, resulting in a generally better constitution of the juvenile allis shad.

Juvenile allis shad in a tank in the pilot facility at the Aquarium La Rochelle
Searching for the first returnees in the Rhine

After it had been found that the juvenile fish in the Rhine had grown and continued to the next stage of their life cycle by migrating to the sea, the burning question remained as to whether these fish would return from the sea to the Rhine after reaching sexual maturity and whether it would be possible to detect the fish in the large river area. On the assumption that about one in 250 stocked allis shad larvae survived the subsequent stages of the life cycle and will return to the Rhine as an adult allis shad, and that about 40 percent of the fish become sexually mature in their fourth and fifth year of life, there was hope that as of the year 2013 (the initial stocking of allis shad in the Rhine took place in 2008), the first returnees could be recorded in the Rhine, in fishways in the Upper Rhine or in the larger tributaries, and that their number would continue to increase between 2014 and 2016.

In fact, an allis shad was observed in a fishway in the Moselle in July 2013 – which was the first allis shad to be seen in the Moselle for 60 years. In the Rhine itself, the search for returnees was more difficult due to maintenance work at the fishway in Iffezheim, which meant that the facility was out of operation during the migration season, and due to a long-lasting flood. However, sensational evidence was found by chance: while monitoring the amount of fish at an extraction point of cooling water from the Upper Rhine, three juvenile allis shad were discovered in September of the same year for the first time. When examining the otoliths, no traces of the oxytetracycline used for marking of the fish were found, meaning that the animals did not originate from the stocking of the LIFE+ project, but were the descendants of allis shad reproducing naturally in the Rhine - the first record of a natural reproduction of allis shad since the extinction of the stock around a hundred years ago. The capture of a demonstrably spawned female allis shad by a professional fisherman in the same section of the Upper Rhine near Karlsruhe in autumn underlines the fact that allis shad do actually spawn in the Rhine. In 2014, when a larger number of allis shad were to be expected due to the intensification of stocking five years earlier, the search for shad was to be intensified.
Conservation and restoration of the Allis shad in the Gironde and Rhine watersheds

Anchored stow-net near Rees at the Lower Rhine

Young-of-the-year juvenile allis shad caught with an anchored stow-net in the Lower Rhine

The first allis shad seen in the river Mosel for 60 years. It was discovered by a VAKI fish counter while climbing the fishway in Koblenz in July 2013.

French fishermen fishing for adult allis shads with floating gill-nets in the Lower Rhine

Estimated number of adult allis returning from the stocking measures based on the numbers of released larvae and an assumed survival rate of 0.4 percent.
Like the juveniles, due to their pelagic lifestyle, adult allis shad are also difficult to track, which means that the monitoring of adult allis shad in a big river like the Rhine presents a significant challenge. The otherwise positive fact that the Rhine is free-flowing for the first 700 kilometres and, unlike the other major rivers in Europe, no interfering dam structures exist which restrict fish migration, in this case makes the search for allis shad difficult because of the large river area. For the search for returnees professional fishermen from the Garonne were hired, who had lived from fishing allis shad until the imposition of the fishing prohibition and therefore knew the migration habits of the species and had mastered the fishing technique of drift net fishing. They therefore succeeded in finding evidence of three adult allis shad in the Lower Rhine at Rees during the monitoring investigation – the first adult allis shad in North Rhine Westphalia which could be identified as returnees from the stocking of the LIFE project by means of the marking of the otolith. This was only to be the beginning of the sensational return of allis shad in the Rhine during 2014. 318 allis shad alone were recorded in the fishways at the barrages of Iffezheim and Gamsheim, whereby both the timing in which the fish were registered at the two successive locations and the differing length distributions suggest that the majority of the fish observed in Gamsheim had migrated over the shipping locks of the Iffezheim barrage and had not been registered in the fishway.

More allis shad were found in the bycatches of professional fishermen in the Upper Rhine or were registered in fishways in the larger tributaries such as Moselle and Neckar, or took the bait of surprised anglers fishing in the Nidda, Lippe and Sieg. Numerous carcasses found in the Rhein indicated that the fish had spawned naturally in the Rhine.

**Resounding success of the reintroduction activities in the Rhine**

Fishway with monitoring station at the Gamsheim dam, the second obstacle for migrating fish in the Rhine

Number of adult allis shad observations in the Rhine between 2000 and 2015
current. Overall an incredible number of 341 adult allis shad were registered in the Rhine system in 2014. Notwithstanding a somewhat lower number of allis shad, which probably were not able to find entry into the fishways due to a long-lasting flood on the Upper Rhine, the wave of returning allis shad (a total of 231) continued in the Rhine in 2015. Numerous carcasses of adult allis shad which died due to spawning activity, are a clear indication that there are several active spawning grounds in the free-flowing stretch of the Rhine. The discovery of numerous juvenile fish which were not all proven as originating from the stocking, but from the natural reproduction of the Rhine returnees, demonstrates that the natural build-up of the stock recurring had begun. When searching for spawning areas of allis shad in the Rhine – due to their characteristic flapping of tail fins on the water surface, the spawning activities of allis shad are audible from a long distance – spawning shad in a characteristic habitat in the Middle Rhine could be heard near Koblenz and thus an active spawning ground was identified.

Curious discovery from an angler on the bank at the middle Rhine near Coblenz: big pike perch suffocated after preying an allis shad of 48 centimetres

Transfer of knowledge and public perception

An important objective of the LIFE+ project is to distribute the project’s contents, findings and achievements at different levels and to make this information available to both those involved in science, planning and management as well as the general public.

The project has the aim, in addition to the technical issues, to connect with the once great cultural and culinary importance of allis shad along the Rhine and, along with associations such as ‘Poller Maigeloog’ dedicated to preserving traditional customs, to revive allis shad festivals.
Parallel to these events, a classroom programme is being conducted in which children learn about the allis shad as an example of the habits of migratory fish, the wildlife of the Rhine and the function of the current as a habitat and migration path, and to release a new generation of allis shad into the Rhine together with politicians and officials. These events, which are carried out annually at different locations along the Rhine in North Rhine-Westphalia, as well as the opening of the pilot facilities for keeping parent allis shad, generated great media interest. Some television reports of the LIFE+ allis shad project can be found on the allis shad YouTube channel along with video documentation of the project.

In exhibitions organised by the project at the Aquarium La Rochelle in France and the Aquazoo Lübbecke Museum in Düsseldorf, hundreds of thousands of visitors can enjoy a unique opportunity to see live allis shad and to learn about the type of conservation and stocking measures taking place under the LIFE+ project.

Being the only project in Europe which is dedicated specifically to the conservation of the species Alosa alosa, the Life+ project is closely linked to national and international institutions and communicates its goals and achievements in conferences and symposia.

At an international symposium in Bergerac, allis shad experts from France, Germany, Portugal, the United Kingdom and North America discussed possible ways in which the critical situation of the allis shad stock in the Gironde region and further allis shad rivers could be overcome in the remaining distribution area of the species, and what lessons can be drawn from the positive re-introduction of allis shad in the Rhine.

In the allis shad school class programme children discover practical knowledge about the allis shad and other communities in the river, particularly these of migratory fish.

Aquarium exhibition at the Aquazoo Löbbecke Museum in Düsseldorf
Conclusion and outlook

The results of studies on the situation of the allis shad and its habitats in the French Gironde region demonstrate the dramatic development of the allis shad stock and short-fall bottlenecks of their migration and reproduction. An independent recovery of the population is not expected due to the alarmingly low levels of the stock of spawning fish on the one hand and also the limited availability of high quality spawning grounds for allis shad. This means that concrete measures must be taken in order to secure the recovery and medium-term increase of the population and to improve the reproductive success of the population. This requires that access to high quality spawning areas must be procured for a larger part of the stock than previously, which presupposes on the one hand the optimisation of the fishways across dam structures or the construction of additional and more appropriate fish migration facilities.

In addition, measures aimed at improving spawning habitats in the lower reaches of rivers would be desirable, in particular regarding the presence of gritty river bed substrate to ensure that developing allis shad eggs are deposited in the gravel gap system and therefore a higher percentage of these eggs will be able to hatch into larvae. Furthermore, measures should urgently be reviewed and then taken that would lead to an improvement in the oxygen saturation in the lower reaches of rivers and ensure the survival of juvenile allis shad migrating to the Gironde estuary.

As a consequence of the successful restocking in the Rhine system it stands to reason that a scientifically oriented stocking programme in the rivers Garonne and Dordogne could also be started: by stocking the rivers with marked allis shad larvae, monitoring investigations could take place to estimate the survival of juveniles in the rivers and to identify deficiencies. With a similar success in stocking to the Rhine system, the spawning stock would also increase in the future as a consequence. In combination with the improvement of the conditions for natural reproduction as described above, a recovery of the stock seems conceivable, and in the best case, renewed fishing
Conservation and restoration of the Allis shad in the Gironde and Rhine watersheds

The LIFE+ Project “Conservation and restoration of the Allis shad in the Gironde and Rhine watersheds” (LIFE09 NAT/DE/000008) was supported by:
